## Abstract

### Background

The origin of low frequency cerebral hemodynamic fluctuations (CHF) in the resting state remains unknown. Breath-by-breath O<sub>2</sub>-CO<sub>2</sub> exchange ratio (bER) has been reported to correlate with the cerebrovascular response to brief breath hold challenge at the frequency range of 0.008–0.03Hz in healthy adults. bER is defined as the ratio of the change in the partial pressure of oxygen ( $\Delta\text{PO}_2$ ) to that of carbon dioxide ( $\Delta\text{PCO}_2$ ) between end inspiration and end expiration. In this study, we aimed to investigate the contribution of respiratory gas exchange (RGE) metrics (bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ ) to low frequency CHF during spontaneous breathing.

### Methods

Twenty-two healthy adults were included. We used transcranial Doppler sonography to evaluate CHF by measuring the changes in cerebral blood flow velocity ( $\Delta\text{CBFv}$ ) in bilateral middle cerebral arteries. The regional CHF were mapped with blood oxygenation level dependent ( $\Delta\text{BOLD}$ ) signal changes using functional magnetic resonance imaging. Temporal features and frequency characteristics of RGE metrics during spontaneous breathing were examined, and the simultaneous measurements of RGE metrics and CHF ( $\Delta\text{CBFv}$  and  $\Delta\text{BOLD}$ ) were studied for their correlation.

### Results

We found that the time courses of  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$  were interdependent but not redundant. The oscillations of RGE metrics were coherent with resting state CHF at the frequency range of 0.008–0.03Hz. Both bER and  $\Delta\text{PO}_2$  were superior to  $\Delta\text{PCO}_2$  in association with CHF while CHF could correlate more strongly with bER than with  $\Delta\text{PO}_2$  in some brain

meet the criteria from Massachusetts General Hospital IRB of Partners HealthCare. regions. Brain regions with the strongest coupling between bER and  $\Delta$ BOLD overlapped with many areas of default mode network including precuneus and posterior cingulate.

## Conclusion

Although the physiological mechanisms underlying the strong correlation between bER and CHF are unclear, our findings suggest the contribution of bER to low frequency resting state CHF, providing a novel insight of brain-body interaction via CHF and oscillations of RGE metrics.

## Introduction

Low frequency components (below 0.05 Hz) in the cerebral hemodynamic fluctuations (CHF) are used to characterize functional connectivity of cerebral resting state networks including the default mode network (DMN) [1, 2]. The origin of these low frequencies of CHF is still not clear, and many physiological candidates of cardiac and respiratory origin had been proposed contributing to this frequency bandwidth [3–6]. They include fluctuations related to respiratory variation (~0.03Hz) [3, 4], heart rate variability (0.05–0.15Hz) [5] and end-tidal carbon dioxide fluctuations (0–0.05Hz) [6].

Fluctuations of respiratory gas exchange (RGE) are of particular interest because RGE is a physiological process of removing carbon dioxide (CO<sub>2</sub>) as a metabolic waste from the blood and replenishing oxygen (O<sub>2</sub>) for energy consumption. Breath-by-breath RGE metrics include parameters like end-tidal partial pressures of O<sub>2</sub> (P<sub>ET</sub>O<sub>2</sub>) and CO<sub>2</sub> (P<sub>ET</sub>CO<sub>2</sub>), changes of the partial pressure of O<sub>2</sub> ( $\Delta$ PO<sub>2</sub>) and CO<sub>2</sub> ( $\Delta$ PCO<sub>2</sub>) [7, 8]. According to the concept of homeostasis, the homeostatic regulatory system is formed with arterial PO<sub>2</sub> and PCO<sub>2</sub> as regulated variables, peripheral and central chemoreceptors as sensors, brain stem as the control center, and diaphragm and respiratory muscles as effectors, to optimize systemic blood gases. While the detailed mechanisms between the change in central chemoreceptor activities and the change in cerebral blood flow (CBF) are topics of on-going research [9–11], arterial PO<sub>2</sub> and PCO<sub>2</sub> which are sensed by chemoreceptors are maintained within a range (or fluctuate) around the physiological ‘set point’ (i.e. mean) by the feedback control of diaphragm and respiratory muscles for ventilation in the homeostatic regulatory system. Spontaneous breathing is, therefore, part of a vital homeostatic process to optimize the systemic blood gases which can presumably regulate in turn CBF and O<sub>2</sub> delivery to the brain [8, 12]. Such homeostatic fluctuations of arterial PO<sub>2</sub> or PCO<sub>2</sub> may interact synergistically and contribute to fluctuations of CHF during spontaneous breathing at rest.

RGE may be related to CHF because oscillations of RGE metrics (P<sub>ET</sub>O<sub>2</sub>, P<sub>ET</sub>CO<sub>2</sub>, respiratory exchange ratio) had been reported to be below 0.05Hz in humans [13, 14]. In our recent breath hold study, we made an emphasis on the ratio of  $\Delta$ PO<sub>2</sub> to  $\Delta$ PCO<sub>2</sub> between end inspiration and end expiration which we named breath-by-breath exchange ratio (bER), to quantify RGE as well [15]. We showed that cerebral hemodynamic responses to brief breath hold challenge were separately coupled with  $\Delta$ PO<sub>2</sub>,  $\Delta$ PCO<sub>2</sub> and bER. It is interesting that bER was superior to either  $\Delta$ PO<sub>2</sub> or  $\Delta$ PCO<sub>2</sub> alone in coupling with the changes of global/regional cerebral hemodynamic response in our breath hold study. In this manuscript, we hypothesized a brain-body interaction during spontaneous breathing where various RGE metrics would separately contribute to CHF and the coupling of CHF with bER would be the strongest. Our study was

different from previous works by Wise et al. [6] and Golestani et al. [16] which assumed that changes of PCO<sub>2</sub> and PO<sub>2</sub> were redundant.

The oscillations of P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub> during spontaneous breathing were shown to be non-redundant by at least three research teams [13, 17, 18] even though the arterial PO<sub>2</sub> and PCO<sub>2</sub> are expected to be correlated with each other through the natural RGE process. Interdependence but non-redundancy were also shown between P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub>, between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>, and between PO<sub>2</sub> and PCO<sub>2</sub> in healthy subjects under brief breath hold challenge [15]. Notably, had P<sub>ET</sub>O<sub>2</sub>/ $\Delta$ PO<sub>2</sub>/PO<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub>/ $\Delta$ PCO<sub>2</sub>/PCO<sub>2</sub> been redundant during spontaneous breathing, there would be no significant oscillations of respiratory exchange ratio as reported by Lenfant et al. [13]. The non-redundancy between P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub> [13, 17, 18] is highly significant because it challenges the long-held belief that the oscillations of the partial pressure of O<sub>2</sub> (PO<sub>2</sub>) and CO<sub>2</sub> (PCO<sub>2</sub>) are simply mirror image of each other [4], and encourages studying the separate effects of O<sub>2</sub>, CO<sub>2</sub> and their ratio bER on CHF during spontaneous breathing.

In addition to the more commonly used P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub>, we focused more on the contribution of RGE metrics including  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> and bER in this manuscript. We preferred to use the ratio of  $\Delta$ PO<sub>2</sub>/ $\Delta$ PCO<sub>2</sub> for the respiratory gas exchange instead of P<sub>ET</sub>CO<sub>2</sub>/P<sub>ET</sub>O<sub>2</sub> with two reasons that we have explained with the findings in our recent breath hold study [15]. First, bER is a ratio which factors out the effects of ventilatory volume fluctuations [7] common to both  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>, but not to both P<sub>ET</sub>CO<sub>2</sub> and P<sub>ET</sub>O<sub>2</sub>. The time courses of P<sub>ET</sub>CO<sub>2</sub> and P<sub>ET</sub>O<sub>2</sub> oscillate out of phase, while  $\Delta$ PO<sub>2</sub> oscillates in phase with  $\Delta$ PCO<sub>2</sub>. Second, bER is a breath-by-breath dynamic form related to the steady-state respiratory exchange ratio (RER) described in the alveolar gas equation introduced by Fenn et al. [19]; the time-averaged value of bER over minutes is therefore mathematically equivalent to the reciprocal of RER.  $\Delta$ PO<sub>2</sub> and not P<sub>ET</sub>O<sub>2</sub> is the designated term used in RER from the alveolar air equation [7, 19].  $\Delta$ PO<sub>2</sub> is used as numerator in bER in this manuscript because of the strong positive correlation found previously between bER and cerebral hemodynamic responses under brief breath hold challenge [15]. RER has been used to evaluate resting systemic metabolic rate [20–22]. There are also technical differences between RER used in the literature and bER we used in this study as well as our previous breath hold study [15]. Traditionally, RER is derived by measuring the respiratory flow and the expired gases collected in Douglas bag connected to a closed circuit over several minutes. In our study, bER was derived by measuring the inspired and expired gases with a nasal tubing at each breath.

Given the dynamic changes in PO<sub>2</sub> and PCO<sub>2</sub> breath-by-breath in humans, we studied RGE metrics as surrogates of arterial blood gases with the recognition of the difference between respiratory metrics and blood gases. We studied the interaction between RGE metrics and CHF measured with transcranial Doppler sonography (TCD) and functional magnetic resonance imaging (fMRI). TCD has an advantage of acquiring data at high temporal resolution (~100 Hz), eliminating the concern of unwanted high frequency cardiovascular signal being aliased into the low frequency range which has a potential association with the minute-long oscillation of RGE metrics. The cerebral blood flow velocities (CBFv) were measured by TCD in the middle cerebral arteries (MCA) which supply most parts of the brain. The application of TCD allows the subjects to have measurements in an upright seated position, which is the usual position in respiratory physiology studies. Although TCD offers a high temporal resolution to evaluate CHF, it does not provide regional information. Regional mapping of spontaneous CHF was carried out instead with blood oxygen level-dependent (BOLD) signal changes measured by fMRI. We used BOLD-fMRI instead of arterial spin labeling (ASL) in MRI perfusion studies for two major reasons. ASL perfusion-related signal has a low contrast to noise ratio in comparison with the BOLD signal, especially in white matter area. ASL image

acquisition at a temporal resolution of 4 seconds also under-samples the spontaneous fluctuations within the respiratory cycle of 4–6 seconds, which hampers the dynamic analyses between CHF and RGE metrics. While CBFv and BOLD signals are not equivalent surrogates for CBF, combining their strengths would be powerful to study the temporal and spatial features in the association between RGE and CHF.

In the present study, we aimed to evaluate the contribution of breath-by-breath RGE metrics to the CHF indicated by CBFv and BOLD signal changes during spontaneous breathing. To address the question of redundancy among RGE metrics during spontaneous breathing, we examined the correlations among bER,  $\Delta\text{PCO}_2$ ,  $\Delta\text{PO}_2$ ,  $\text{P}_{\text{ET-CO}_2}$  and  $\text{P}_{\text{ET-O}_2}$ . In the TCD study, we measured the correlation of CBFv in the MCA with RGE metrics of bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ . We also examined the temporal features and frequency characteristics of these RGE metrics and their coherence with CBFv. In the fMRI study, we mapped the association between regional BOLD signal changes and RGE metrics of bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ . Brain regions showing a significant association between regional BOLD signal changes and RGE metrics were then compared with regions within the default mode network (DMN) outlined by the resting state connectivity analysis with the seed at the left precuneus. DMN encompasses brain regions responsible for the constant background activities at rest, showing higher metabolic and hemodynamic level than the other parts of the cortex [23]. The temporal features and frequency characteristics of these RGE metrics and their coherence with BOLD signal changes in the regions within DMN were also examined. The respiratory metric of respiration volume per unit time (RVT) was also derived to examine if the potential coherence between CHF and RGE metrics were resulting from respiratory variability. The investigation of the association between RGE metrics and CHF would provide new directions to the study of brain-body interaction, in addition to offering a physiological model to characterize the contribution of gas exchange elements in the low frequency resting state fluctuations, With the reference of cerebrovascular reactivity (CVR) to exogenous CO<sub>2</sub> challenge, the potential of using the interaction between CHF and RGE metrics to evaluate CVR to the elements in spontaneous breathing was also discussed.

## Materials and methods

### Participants

Twenty-two volunteers aged from 19 to 48 years (mean age = 30.5 years, SD = 9.1 years, 14 males and 8 females) were included. Eleven of them participated in both TCD and MRI sessions, while the remaining participated in either one of the sessions. Subject demographics were shown in Table 1. All of them were recruited by e-mail and poster placement within the Partners hospital network. They were screened to exclude neurological, mental and medical disorders and drug abuse. TCD and MRI scanning were performed in the Athinoula A. Martinos Center for Biomedical Imaging at the Massachusetts General Hospital of Partners HealthCare. All the experimental procedures were explained to the subjects, and signed informed consent was obtained prior to the participation in the study. All components of this study were performed in compliance with the Declaration of Helsinki, and all procedures were approved by the Massachusetts General Hospital IRB of Partners HealthCare.

Our study was divided into two parts: Part I and Part II. In Part I TCD study, we aimed to correlate the RGE metrics including bER,  $\Delta\text{PCO}_2$  and  $\Delta\text{PO}_2$  with CBFv in MCAs which serve as CHF in the major cerebral arterial supply during spontaneous breathing. We also examined the temporal features and frequency characteristics of these RGE metrics and their coherence with CBFv. Thirteen subjects participated in TCD sessions. In Part II MRI study, we aimed to map the association between these RGE metrics (bER,  $\Delta\text{PCO}_2$  and  $\Delta\text{PO}_2$ ) and BOLD signal

changes which serve as regional CHF during spontaneous breathing. Twenty subjects participated in MRI sessions. Ten out of 20 subjects had additional exogenous CO<sub>2</sub> challenge in the MRI sessions. Before we correlated the changes of RGE with CBFv and BOLD signal changes, we examined the correlations among the respiratory metrics (bER,  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub>) acquired in both TCD and MRI sessions.

## Part 1: TCD

**Transcranial Doppler scanning.** Before the study of blood flow velocity in intracranial arteries, the subject was allowed to rest at least 20–30 minutes in an upright seated position for hemodynamic stabilization. The blood pressure measured in the subject was within the normal range of systolic blood pressure below 130 mmHg [24]. With the subject in an upright seated position, a dual probe setting with 2MHz transducers in conjunction with TCD system (Delicate EMS-9U, Shenzhen, China) was used for simultaneous recording of CBFv in the MCA on both left and right sides while the subject was at rest. Two transducers were attached to the left and right temporal bone windows by velcro. The depth of the Doppler samples was confined to the M1 segment, which is at the main stem of the MCA, for all the subjects.

A white crosshair in the black background was presented visually to the subject by a computer using the software Eprime Professional 2.0 (Psychology Software Tools, Inc., Pittsburgh, USA) to fixate their eye movement. The total duration of the CBFv data acquisition lasted 10 minutes.

Physiological changes including PCO<sub>2</sub>, PO<sub>2</sub>, electrocardiogram (ECG) and peripheral blood pressure were measured simultaneously with TCD acquisition. A biological amplifier (FE132, ADInstruments, Inc., CO, USA) and a finometer (Finapres Medical Systems, Netherlands) were used to measure ECG and peripheral blood pressure, respectively. A small nasal tubing was placed at the subject's nostril to sample PCO<sub>2</sub> and PO<sub>2</sub> via gas analyzers (Capstar-100, Oxystar-100, CWE, Inc., PA, USA) after calibrating to the barometric pressure on the day of TCD session and correcting for vapor pressure. Small nasal tubing was chosen to sample PCO<sub>2</sub> and PO<sub>2</sub> because of several reasons. In the current study, we standardized all the physiological set-up in both TCD and MRI sessions. We did not measure PCO<sub>2</sub> and PO<sub>2</sub> from a face-mask connected to a closed breathing circuit with non-rebreathing valves because of the space constraint of the MRI head coil, or from the expired gases collected in Douglas bag because of the slow sampling of gases in the units of minutes. Sampling gases with small nasal tubing has an advantage that the subjects breathe normally through the nose. In the gas sampling circuit, the same gas sample volume was used in both CO<sub>2</sub> and O<sub>2</sub> analyzers at the same gas sampling flow rate. The CBFv and physiological measurements were synchronized using trigger signals from E-prime. All the CBFv time series and physiological recordings were stored for offline data analysis.

## Part 2: MRI

**MRI acquisition.** MRI brain scanning was performed on a 3-Tesla scanner (Siemens Medical, Erlangen, Germany). The head was immobilized in a standard head coil with foam pads. The following whole brain MRI datasets were acquired on each subject: 1) standard high-resolution sagittal images acquired with volumetric T1-weighted 3D-MEMPRAGE (TR = 2530ms, TE = 1.74ms/3.6ms/5.46ms/7.32ms, flip angle = 7°, FOV = 256×256mm, matrix = 256×256, slice thickness = 1mm); 2) BOLD-fMRI images acquired with gradient-echo echo planar imaging (EPI) sequence (TR = 1450ms, TE = 30ms, flip angle = 90°, FOV = 220×220mm, matrix = 64×64, thickness = 5mm, slice gap = 1mm) while the subject was at rest. The visual presentation of the crosshair, the physiological set-up for the sampling of PCO<sub>2</sub> and PO<sub>2</sub> in the MRI session were the same as those used in the TCD session. The gas analyzers were again calibrated to the barometric pressure on the day of MRI session and corrected for vapor pressure. ECG was measured using a Siemens physiological monitoring unit (Siemens Medical, Erlangen, Germany). Physiological changes including PCO<sub>2</sub>, PO<sub>2</sub>, ECG and respiration were measured simultaneously with MRI acquisition. All the physiological measurements, including those of PCO<sub>2</sub>, PO<sub>2</sub> and ECG were synchronized using trigger signals from the MRI scanner. BOLD-fMRI images and physiological recordings were stored for offline data analysis.

**Exogenous CO<sub>2</sub> challenge.** Ten out of 20 subjects had additional exogenous CO<sub>2</sub> challenge in the MRI sessions. An in-house gas delivery and mixing system comprising of a medical gas mixer in series with a manifold of flow meters was used to mix and deliver gas mixture for exogenous CO<sub>2</sub> challenge. Given that there is significant inter-individual variance in resting P<sub>ET</sub>CO<sub>2</sub> [25], resting P<sub>ET</sub>CO<sub>2</sub> was assessed in subjects via calibrated capnograph before the exogenous CO<sub>2</sub> challenge. The subject wore nose-clip and breathed through a mouth-piece on an MRI-compatible circuit designed to maintain the P<sub>ET</sub>CO<sub>2</sub> within ± 1–2 mmHg of target P<sub>ET</sub>CO<sub>2</sub> [26, 27]. The fraction of inspired carbon dioxide was adjusted to produce steady-state conditions of normocapnia and mild hypercapnia (4–8 mmHg above the subject's resting P<sub>ET</sub>CO<sub>2</sub>). The CO<sub>2</sub> challenge paradigm consisted of 2 consecutive phases (normocapnia and mild hypercapnia) repeating 6 times with 3 epochs of 4 mmHg increase and 3 epochs of 8 mmHg increase of P<sub>ET</sub>CO<sub>2</sub>. The normocapnic phase lasted 60–90 seconds, while the mild

hypercapnic phase lasted 30 seconds. The same paradigm was also used and described in our other study [15]. The total duration of the exogenous CO<sub>2</sub> hypercapnic challenge lasted 10 minutes.

When the subject had exogenous CO<sub>2</sub> challenge in MRI session, BOLD-fMRI images were acquired using the same EPI sequence for resting state. The PCO<sub>2</sub> and PO<sub>2</sub> were sampled through the air filter connected with the mouthpiece, and the sampled gases were measured by calibrated gas analyzers. The respiratory flow was measured with respiratory flow head (MTL300L, ADInstruments, Inc., CO, USA) on the breathing circuit via calibrated spirometer (FE141, ADInstruments, Inc., CO, USA). The physiological measurements were synchronized with MRI images using trigger signals from the MRI scanner. All the BOLD-fMRI images and physiological recordings were stored for offline data analysis.

## Data analysis

**Processing of physiological data.** The physiological data from both TCD and MRI sessions were analyzed using Matlab R2014a (Mathworks, Inc., Natick, MA, USA). Technical delay of PCO<sub>2</sub> and PO<sub>2</sub> was corrected by cross-correlating the time series of PCO<sub>2</sub> and PO<sub>2</sub> with respiratory phases determined from the artifactual displacement due to chest excursion on ECG time series in the TCD sessions, with the respiratory phases from respiratory bellow or respiratory flow measured with respiratory flow head via spirometer in the MRI sessions.

End inspiration (I) and end expiration (E) were defined on the time series of PO<sub>2</sub> and PCO<sub>2</sub> (S1 Fig). The breath-by-breath P<sub>ET</sub>CO<sub>2</sub> and P<sub>ET</sub>O<sub>2</sub> were extracted at the end expiration of PCO<sub>2</sub> and PO<sub>2</sub> time series respectively.  $\Delta$ PO<sub>2</sub> is defined as (inspired PO<sub>2</sub> - expired PO<sub>2</sub>) and  $\Delta$ PCO<sub>2</sub> is defined as (expired PCO<sub>2</sub> - inspired PCO<sub>2</sub>). Breath-by-breath O<sub>2</sub>-CO<sub>2</sub> exchange ratio (bER) is defined as the ratio of  $\Delta$ PO<sub>2</sub> to  $\Delta$ PCO<sub>2</sub> measured between end inspiration and end expiration at each breath, whereas RER at steady state from alveolar air equation introduced by Fenn et al. [19] is formulated as the ratio of  $\Delta$ PCO<sub>2</sub> to  $\Delta$ PO<sub>2</sub> over minutes. The product of  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> was not used to evaluate the interaction with CHF because the effects of fluctuations due to ventilation would be exacerbated in  $\Delta$ PO<sub>2</sub> ×  $\Delta$ PCO<sub>2</sub> (S2 Fig).

Simple correlation analyses were applied to the time series of RGE metrics (bER,  $\Delta$ PCO<sub>2</sub>, and  $\Delta$ PO<sub>2</sub>) in pairs. The correlation was considered significant at  $p < 0.05$ .

## Part 1

**Preprocessing of CBFv data.** The CBFv data were analyzed using Matlab R2014a (Mathworks, Inc., Natick, MA, USA). A median filter was applied to the data to reduce artifactual spikes. Beat-by-beat systolic peaks and end-diastolic troughs were determined using custom Matlab function and corrected on the graphical user interface incorporated in the function. Systolic peaks and diastolic troughs of cardiac cycles on the CBFv time series showing persistent artifacts were excluded in the following analysis. TCD data in both left and right MCAs were acquired on 13 subjects. One of the 13 TCD datasets had persistent artifacts in over one-third of the CBFv time series acquired in the LMCA, and another one had persistent artifacts in CBFv data acquired in RMCA. The CBFv time series of those particular TCD runs that showed persistent artifacts were excluded in further analysis, and the CBFv time series acquired in the contralateral MCA that did not show persistent artifacts were retained. Time series of mean CBFv were derived by integrating the CBFv over each cardiac cycle. To reduce the large inter-individual variations of absolute blood flow velocities [28, 29] and to remove the dependence of insonation angle [30], the percent change of CBFv ( $\Delta$ CBFv) relative to baseline value in the left and right MCAs was derived. The mean CBFv for 30 seconds at the beginning of the time series was chosen as the baseline.

**Correlation analyses between  $\Delta$ CBFv and RGE metrics.** The time series of  $\Delta$ CBFv were correlated with those of bER,  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub> separately. The correlation indicated by Pearson's correlation coefficient was considered significant at  $p < 0.05$ . Fisher's Z-transformation was used to transform Pearson's correlation coefficients to Fisher's z scores for group analysis. Paired t-tests were used to compare the Fisher's z scores representing the correlation between  $\Delta$ CBFv and bER with those indicating the correlation between  $\Delta$ CBFv and other physiological parameters besides bER. Differences were considered to be significant at  $p < 0.05$ . We did not apply a low pass filter to CHF before our correlation analyses, even though applying a low pass filter to CHF is a standard preprocessing step in the resting state analysis [1].

**Dynamic analysis of coherence between  $\Delta$ CBFv and RGE metrics as a function of time and frequency.** Wavelet transform coherence (WTC) was employed to demonstrate the dynamic interaction between  $\Delta$ CBFv and RGE metrics (S3 Fig) in the time-frequency domain. WTC is a method for analyzing the coherence and phase lag between two time series as a function of both time and frequency [31, 32]. The temporal and phase information of WTC has been used to map the dynamic connectivity of the brain regions related to heart rate changes [33]. It is therefore well suited to investigate the dynamic changes in the coupling between the time series of  $\Delta$ CBFv and RGE metrics including bER,  $\Delta$ PCO<sub>2</sub>, and  $\Delta$ PO<sub>2</sub>, as well as the phase lag of  $\Delta$ CBFv to bER,  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub>. We used the Matlab wavelet cross-spectrum toolbox developed by Grinsted et al. [32]. Squared wavelet coherence between the time series of each RGE metric and  $\Delta$ CBFv was separately plotted with x-axis as time and y-axis as a scale which has been converted to its equivalent Fourier period. An example of squared wavelet coherence between bER and  $\Delta$ CBFv in right MCA from a representative subject during spontaneous breathing is shown in S3B Fig. The magnitude of wavelet transform coherence ranged between 0 and 1 that can be conceptualized as a localized correlation coefficient in time and frequency space [32]. An arrow indicates the phase angle between the two time series, with bER leading  $\Delta$ CBFv, at particular samples of the time-frequency plane: a rightward pointing arrow indicates that the time series are in phase, or positively correlated ( $\phi = 0$ ); a leftward pointing arrow indicates anti-correlation ( $\phi = \pi$ ), and the downward and upward pointing arrows indicate phase angles of  $\pi/2$  and  $-\pi/2$  relative to  $\phi = 0$ , respectively. Areas inside the 'cone of influence', which are locations in the time-frequency plane where edge effects give rise to lower confidence in the computed values, are shown in faded color outside of the conical contour. The statistical significance level of the wavelet coherence is estimated using the Monte Carlo method, and the 5% significance level against red noise is shown as a thick contour in the squared wavelet coherence plot. The wavelet coherence magnitudes and phases bounded by thick contour outside the cone of influence are considered significant.

Time-averaged coherence is defined as the total significant coherence at each scale of Fourier periods (converted into frequency) where the wavelet coherence magnitude exceeded 95% significance level, normalized by the maximum possible coherence outside the cone of influence at that particular scale (S3C Fig). It is interpreted in a similar way as the coherence in the transfer function analysis which has been used in cerebral autoregulation study [34].

Interpreting the time-averaged coherence irrespective of phase lag raised the question that the coherence with positive correlation between two time series (at phase lag of  $0 \pm \pi/2$ ) and the coherence with negative correlation (at phase lag of  $\pi \pm \pi/2$ ) might be mixed together. Therefore, mean time-averaged coherence at the phase lags of  $0 \pm \pi/2$  and  $\pi \pm \pi/2$  were separately averaged across all the subjects who participated in the TCD sessions to explore the Fourier periods/frequency bandwidths that oscillations of  $\Delta$ CBFv were in synchrony with the time series of each RGE metric (bER,  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub>) when they were at rest.

## Part 2

**Preprocessing of BOLD-fMRI data.** All the BOLD-fMRI data were imported into the software Analysis of Functional NeuroImage (AFNI) [35] (National Institute of Mental Health, <http://afni.nimh.nih.gov>) for time-shift correction, motion correction, normalization and detrending. Details of preprocessing with AFNI are given as follows. The first 12 volumes in the first 12 time points of each functional dataset, collected before equilibrium magnetization was reached, were discarded. Each functional dataset was corrected for slice timing, motion-corrected and co-registered to the first image of the functional dataset using three-dimensional volume registration. Components of motion were removed from the co-registered functional dataset using orthogonal projection. The clean functional dataset was then normalized to its mean intensity value across the time-series. Voxels located within the ventricles and outside the brain defined in the parcellated brain volume using FreeSurfer [36, 37] (MGH/MIT/HMS Athinoula A. Martinos Center for Biomedical Imaging, Boston, <http://surfer.nmr.mgh.harvard.edu>) were excluded from the following analyses of functional images. Individual subject brain volumes with time series of percent BOLD signal changes ( $\Delta$ BOLD) were derived.

**Linear regression for the association between  $\Delta$ BOLD and RGE metrics in individual subject.** Linear regression analysis was used to evaluate the association between  $\Delta$ BOLD, bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> for each subject. For each voxel of the preprocessed brain volume, the time series of  $\Delta$ BOLD was separately regressed on bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>. Regression coefficient beta ( $\beta$ ) value was defined as the percent BOLD signal changes per unit change of the regressor (bER,  $\Delta$ PO<sub>2</sub> or  $\Delta$ PCO<sub>2</sub>). Individual subject brain volumes with  $\beta$  magnitudes were registered onto their own anatomical scans and transformed to the standardized space of Talairach and Tournoux [38]. Monte Carlo simulation was used to correct for multiple comparisons [39]. To protect against type I error, individual voxel probability threshold of  $p < 0.005$  was held to correct the overall significance level to  $\alpha < 0.05$ . Based upon a Monte Carlo simulation with 2000 iteration processed with ClustSim program [40], it was estimated that a 476mm<sup>3</sup> contiguous volume would provide the significance level  $\alpha < 0.05$ , which met the overall corrected threshold of  $p < 0.05$ .

**Group region-of-interest (ROI) analysis for the association between  $\Delta$ BOLD and RGE metrics.** For each subject who participated in MRI scanning,  $\beta$  magnitude values derived by regressing  $\Delta$ BOLD on bER ( $\beta_{\text{bER}}$ ),  $\Delta$ BOLD on  $\Delta$ PO<sub>2</sub> ( $\beta_{\Delta\text{PO}_2}$ ) and  $\Delta$ BOLD on  $\Delta$ PCO<sub>2</sub> ( $\beta_{\Delta\text{PCO}_2}$ ) were separately averaged in each of the 160 brain regions parcellated by the software FreeSurfer. One-sample t-tests were used to analyze regional  $\beta_{\text{bER}}$ ,  $\beta_{\Delta\text{PO}_2}$  and  $\beta_{\Delta\text{PCO}_2}$  in the subject group. False discovery rate was used to correct for multiple comparisons [41, 42]. Significant association in group was considered at false discovery rate adjusted  $p_{\text{fdr}} < 0.05$ .

For each brain region, we also calculated the number of voxels with significant  $\Delta$ BOLD that reached cluster-corrected threshold  $p < 0.05$  in the individual subject analysis. The number of voxels with significant  $\Delta$ BOLD were then normalized to the total number of voxels in each brain region. The percentage of voxels in each brain region with significant  $\Delta$ BOLD, namely  $\text{voxel}\beta_{\text{bER}}$ ,  $\text{voxel}\beta_{\Delta\text{PO}_2}$  and  $\text{voxel}\beta_{\Delta\text{PCO}_2}$ , for RGE metrics bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> were calculated respectively. Individual subject brain volumes with regional  $\text{voxel}\beta$  due to bER ( $\text{voxel}\beta_{\text{bER}}$ ),  $\Delta$ PO<sub>2</sub> ( $\text{voxel}\beta_{\Delta\text{PO}_2}$ ) and  $\Delta$ PCO<sub>2</sub> ( $\text{voxel}\beta_{\Delta\text{PCO}_2}$ ) were obtained. One-sample t-tests were used to analyze regional  $\text{voxel}\beta_{\text{bER}}$ ,  $\text{voxel}\beta_{\Delta\text{PO}_2}$  and  $\text{voxel}\beta_{\Delta\text{PCO}_2}$  in the subject group. False discovery rate was used to correct for multiple comparisons [41, 42]. Significant association in group was considered at  $p_{\text{fdr}} < 0.05$ .

In the group analysis, we preferred the ROI analysis of 160 brain regions for  $\beta_{\text{bER}}$ ,  $\beta_{\Delta\text{PO}_2}$  and  $\beta_{\Delta\text{PCO}_2}$  instead of the commonly used voxel-by-voxel analysis because the maps of  $\beta$  values were compared side-by-side with the maps of  $\text{voxel}\beta_{\text{bER}}$ ,  $\text{voxel}\beta_{\Delta\text{PO}_2}$  and  $\text{voxel}\beta_{\Delta\text{PCO}_2}$  which

require the ROI analysis to evaluate the percentage of voxels in each brain region with significant  $\Delta$ BOLD.

**Group maps of regional  $\Delta$ BOLD associated with RGE metrics vs. group functional connectivity maps with the seed at left precuneus.** Seed-based analysis with the seed at the left precuneus was used to generate the functional connectivity map for an individual subject. For each subject, after preprocessing of BOLD data, a low pass filtering at 0.03Hz was applied onto the brain volume with time series of  $\Delta$ BOLD. The time series of  $\Delta$ BOLD in the voxels within left precuneus were averaged. The averaged  $\Delta$ BOLD time series of left precuneus was correlated with the  $\Delta$ BOLD time series of each voxel in the brain volume. Pearson's correlation coefficient was used to indicate the strength of correlation and converted to z scores using the Fisher's Z transformation. For the comparison with the regional  $\beta$  and voxel $\beta$  maps, the Fisher's z scores in each of the 160 brain regions were averaged for each subject. Individual subject brain volumes with regional Fisher's z scores from all the subjects who participated in MRI sessions were subjected to group analysis using a one-sample t-test. False discovery rate was again used to correct for multiple comparisons [39, 41, 42]. Significant correlation in group was considered at  $p_{\text{FDR}} < 0.05$ .

**Dynamic analysis of coherence between bER and  $\Delta$ BOLD in brain regions within DMN.** To further verify the dynamic coupling between bER and CHF in DMN, we used the WTC method to examine the dynamic changes in coupling between the time series of RGE metrics (bER,  $\Delta$ PCO<sub>2</sub>, and  $\Delta$ PO<sub>2</sub>) and  $\Delta$ BOLD in three brain regions within DMN. They included inferior parietal lobule (IPL), posterior cingulate (PCC) and precuneus (PCun). The analysis procedures were the same as those described for the dynamic analysis of coherence between  $\Delta$ CBFv and RGE metrics. The mean time-averaged coherence between each RGE metric and  $\Delta$ BOLD from each of the three brain regions at the phase lag of  $0 \pm \pi/2$  was averaged across all the subjects who participated in MRI sessions. Similarly, the mean time-averaged coherence between each RGE metric and  $\Delta$ BOLD from each of the three brain regions at the phase lags of  $\pi \pm \pi/2$  were averaged across the same group of the subjects.

**Dynamic analysis of coherence between respiratory volume per unit time (RVT) and  $\Delta$ BOLD in brain regions within DMN.** To confirm that the respiratory-variation-related fluctuations reported by Birn et al. [3] had little contribution to CHF within the DMN, we used the same WTC method to examine the dynamic changes in coupling between the time series of RVT (respiration volume per time) and  $\Delta$ BOLD in three brain regions within DMN (IPL, PCC and PCun). Ten out of 20 subjects had RVT measurements with a respiratory bellow. According to the method described by Birn et al. [3], RVT was computed by the difference between the maximum and minimum bellow positions at the peaks of inspiration and expiration respectively, and this difference was then divided by the period of the respiratory cycle. The mean time-averaged coherence between RVT and  $\Delta$ BOLD from each of the three brain regions at the phase lag of  $0 \pm \pi/2$  were averaged across 10 subjects. Similarly, the mean time-averaged coherence between RVT and  $\Delta$ BOLD from each of the three brain regions at the phase lag of  $\pi \pm \pi/2$  were averaged across the same group of subjects.

**Regional CVR quantification under exogenous CO<sub>2</sub> challenge.** Linear regression analysis was used to derive CVR from the time series of  $\Delta$ BOLD and vasoactive stimulus when the subject was under exogenous CO<sub>2</sub> challenge. We used the time series of P<sub>ET</sub>CO<sub>2</sub> a regressor in a linear regression analysis. CVR under exogenous CO<sub>2</sub> challenge was defined as the percent BOLD signal changes per mmHg change of P<sub>ET</sub>CO<sub>2</sub>. Therefore CVR was quantified by the coefficient of regression, i.e. the slope.

For each subject who participated in exogenous CO<sub>2</sub> MRI scanning, CVR values derived from regressing  $\Delta$ BOLD on P<sub>ET</sub>CO<sub>2</sub> (CVR<sub>CO<sub>2</sub>-PETCO<sub>2</sub></sub>) were separately averaged in each of the 160 brain regions parcellated by the software FreeSurfer. To study the CVR in group, one-

sample t-tests were applied onto the brain volumes with regional  $CVR_{CO_2-PETCO_2}$ . False discovery rate was used to correct for multiple comparisons.

## Results

Subject demographics are shown in [Table 1](#). The mean values and standard deviation of the time series of  $P_{ET}CO_2$ ,  $P_{ET}O_2$ ,  $\Delta PCO_2$ ,  $\Delta PO_2$  and bER measured in the TCD and MRI sessions are summarized in [Table 2](#).

### Correlation among bER, $\Delta PO_2$ and $\Delta PCO_2$

The correlations among the RGE metrics (bER,  $\Delta PO_2$  and  $\Delta PCO_2$ ) in TCD and MRI sessions are shown in [Fig 1](#) and summarized in [S1 Table](#). Correlation coefficients between  $\Delta PO_2$  and  $\Delta PCO_2$  ranged from 0.7 to 0.9 in TCD sessions and from 0.2 to 0.9 in MRI sessions, demonstrating that  $\Delta PO_2$  and  $\Delta PCO_2$  are not necessarily redundant in either TCD or MRI sessions. The range of correlation strength between  $\Delta PO_2$  and  $\Delta PCO_2$  in the MRI sessions was larger than that in TCD sessions. Correlation between bER and  $\Delta PO_2$  was stronger than that between bER and  $\Delta PCO_2$ .

### Part 1

**Correlation between  $\Delta CBFv$  and RGE metrics.** The time series of  $\Delta CBFv$  in the right MCA of a representative subject during spontaneous breathing with and without applying low pass filtering at 0.03Hz are shown in [Fig 2A](#). The time series of bER,  $\Delta PO_2$ ,  $\Delta PCO_2$ ,  $P_{ET}CO_2$  and  $P_{ET}O_2$  acquired simultaneously with  $\Delta CBFv$  for the same subject are shown in [Fig 2B](#). All the time series including  $CBFv$ , bER,  $\Delta PO_2$ ,  $\Delta PCO_2$ ,  $P_{ET}CO_2$  and  $P_{ET}O_2$  of the representative subject showed prominent oscillations with periods of 0.5 to 2 minutes which is equivalent to the frequency range of 0.008Hz to 0.03Hz. Oscillations of bER,  $\Delta PO_2$ ,  $\Delta PCO_2$ ,  $P_{ET}CO_2$  were in phase with  $CBFv$ , while the oscillations of  $P_{ET}O_2$  were out of phase. Oscillation amplitude of  $\Delta PO_2$  could double that of  $\Delta PCO_2$  ([Fig 2B](#)), where the standard deviation values indicating variations over the  $\Delta PO_2$  time series were larger than those over the  $\Delta PCO_2$  time series as shown in [Table 2](#).

With the simple correlation analyses, [Fig 2C](#) shows that the correlation of bER with  $\Delta CBFv$  was the strongest among all the RGE metrics for the representative subject.  $\Delta PO_2$  followed relatively closely behind bER, and  $\Delta PCO_2$  was the weakest in correlation with  $\Delta CBFv$ .  $\Delta PCO_2$  and  $P_{ET}CO_2$  shared very similar correlation results with  $\Delta CBFv$ . The correlation coefficients between  $\Delta CBFv$  and RGE metrics (bER,  $\Delta PO_2$ ,  $\Delta PCO_2$  and  $P_{ET}CO_2$ ) for all 13 subjects who participated in TCD sessions are shown in [S2 Table](#). The similar correlation of bER and  $\Delta PO_2$  with  $\Delta CBFv$  showed that  $\Delta PO_2$  plays an essential role in bER correlation with CHF.

Applying a low pass filter of 0.03Hz to the time series of  $\Delta CBFv$  ([Fig 2A](#), right panel) increased the strength of correlation of  $CBFv$  with bER,  $\Delta PO_2$  and  $\Delta PCO_2$  ([Fig 2C](#), right panel) but did not change the order of which RGE metric was more correlated with  $\Delta CBFv$ .

In the group analysis, paired comparisons of Fisher's z scores transformed from Pearson's correlation coefficients between  $\Delta CBFv$  and RGE metrics for all 13 subjects are shown in [Fig 2D](#) and [S2 Table](#). The Fisher's z scores of the correlation between  $\Delta CBFv$  and bER were used as a reference to compare with those of the correlation between  $\Delta CBFv$  and other RGE metrics beside bER.  $\Delta CBFv$  consistently showed a stronger correlation with bER and  $\Delta PO_2$  than with  $\Delta PCO_2$  and  $P_{ET}CO_2$ . The correlation of  $\Delta CBFv$  in LMCA with bER was significantly stronger than that with  $\Delta PO_2$ , while the difference between the correlation of  $\Delta CBFv$  in RMCA with bER and that with  $\Delta PO_2$  did not reach statistical significance.

Mean values (SD) of P<sub>ET</sub>CO<sub>2</sub>, P<sub>ET</sub>O<sub>2</sub>, ΔPCO<sub>2</sub>, ΔPO<sub>2</sub> and bER for all subjects who participated in the TCD sessions (n = 13) (left), and for those who participated in the MRI sessions (n = 20) (right).

<https://doi.org/10.1371/journal.pone.0238946.t002>

The differences revealed in paired comparisons again demonstrated that ΔPO<sub>2</sub> and ΔPCO<sub>2</sub> were not necessarily redundant.

**Dynamic coherence between ΔCBFv and RGE metrics.** The time-averaged coherence analyzed by WTC at the phase lag of 0±π/2 which indicates a positive correlation, and at the

**Fig 1. Correlation among breath-by-breath RGE metrics during spontaneous breathing.** (A) Correlations among breath-by-breath RGE metrics (bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ ) in all subjects who participated in TCD sessions, and (B) those who participated in MRI sessions. Each gray circle represents the Pearson's correlation coefficient from the correlation analysis of the time series of parameter pair shown on the x-axis for each subject. The thick middle horizontal line, the box and the vertical rod represent the mean, 95% confidence interval and standard deviation of the group data, respectively.

<https://doi.org/10.1371/journal.pone.0238946.g001>

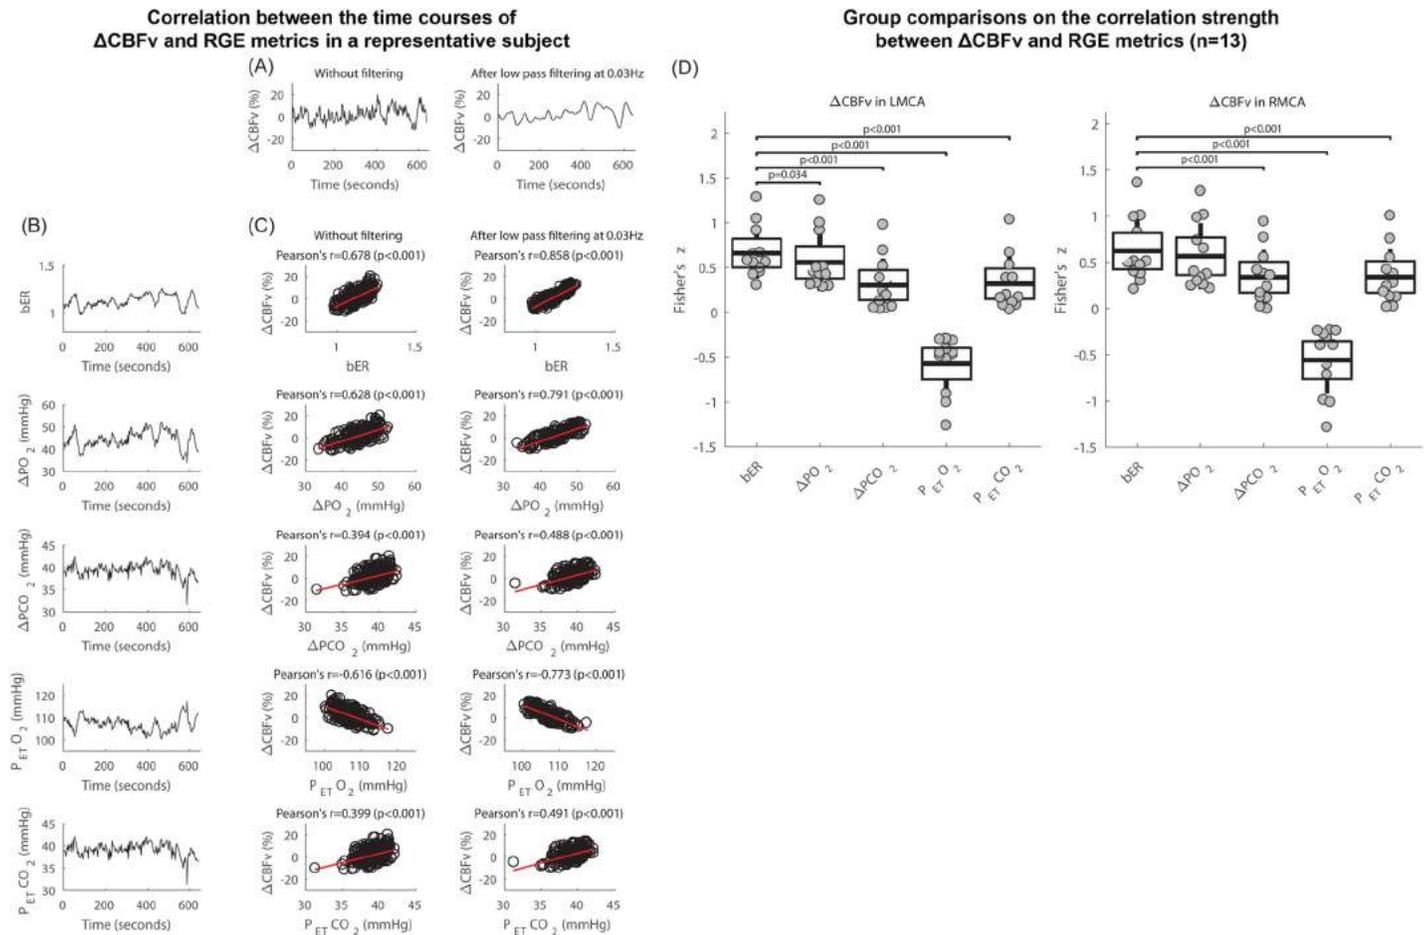

phase lag of  $\pi \pm \pi/2$  which indicates a negative correlation, were plotted for all 13 subjects participated in TCD sessions (Fig 3). At the phase lag of  $0 \pm \pi/2$ , the mean time-averaged coherence between bER and  $\Delta\text{CBFv}$  and that between  $\Delta\text{PO}_2$  and  $\Delta\text{CBFv}$  reached a value of 0.5 or above at the frequency range between 0.008 and 0.03Hz, while the mean time-averaged coherence between  $\Delta\text{PCO}_2$  and  $\Delta\text{CBFv}$  stayed below 0.1 (Fig 3A, top row). At the phase lag of  $\pi \pm \pi/2$ , the mean time-averaged coherence of all three RGE metrics with  $\Delta\text{CBFv}$  stayed below 0.1 at the frequency range between 0.008 and 0.03Hz (Fig 3B, top row).

## Part 2

**Association between  $\Delta\text{BOLD}$  and RGE metrics in different brain regions.** Brain maps on the association between  $\Delta\text{BOLD}$  and RGE metrics (bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ ) during spontaneous breathing in a representative subject are shown in S4A Fig. The regional  $\beta$  magnitudes, namely  $\Delta\text{BOLD}$  per unit change of each RGE metric in different brain regions, were mapped for bER ( $\beta_{\text{bER}}$ ),  $\Delta\text{PO}_2$  ( $\beta_{\Delta\text{PO}_2}$ ) and  $\Delta\text{PCO}_2$  ( $\beta_{\Delta\text{PCO}_2}$ ) (S4A Fig). Comparing with the maps of  $\beta_{\Delta\text{PO}_2}$  or  $\beta_{\text{bER}}$ , the map of  $\beta_{\Delta\text{PCO}_2}$  showed fewer pixels which reached statistical significance (corrected  $p < 0.05$ ).

In addition to the brain maps from the individual subject, group regional  $\beta$  magnitudes were mapped for bER ( $\beta_{\text{bER}}$ ),  $\Delta\text{PO}_2$  ( $\beta_{\Delta\text{PO}_2}$ ) and  $\Delta\text{PCO}_2$  ( $\beta_{\Delta\text{PCO}_2}$ ) for all 20 subjects who participated in MRI sessions (S4B Fig and Fig 4A).  $\Delta\text{BOLD}$  was found to be significantly associated with bER or  $\Delta\text{PO}_2$  in most of the brain regions (Fig 4A) while association found between  $\Delta\text{BOLD}$  and  $\Delta\text{PCO}_2$  in a few brain regions (insula, medial orbitofrontal and temporal) (S4B Fig) did not reach statistical significance after correcting for multiple comparisons (Fig 4A).

In addition to using the  $\beta$  magnitude, brain volumes with the regional percentage of voxels having significant  $\Delta\text{BOLD}$  for the regressors bER ( $\text{voxel}\beta_{\text{bER}}$ ),  $\Delta\text{PO}_2$  ( $\text{voxel}\beta_{\Delta\text{PO}_2}$ ) and  $\Delta\text{PCO}_2$  ( $\text{voxel}\beta_{\Delta\text{PCO}_2}$ ) were analyzed in the same group of 20 subjects. Significant association of  $\Delta\text{BOLD}$  with bER and  $\Delta\text{PO}_2$  was shown in more than 50% of the voxels in the gray matter

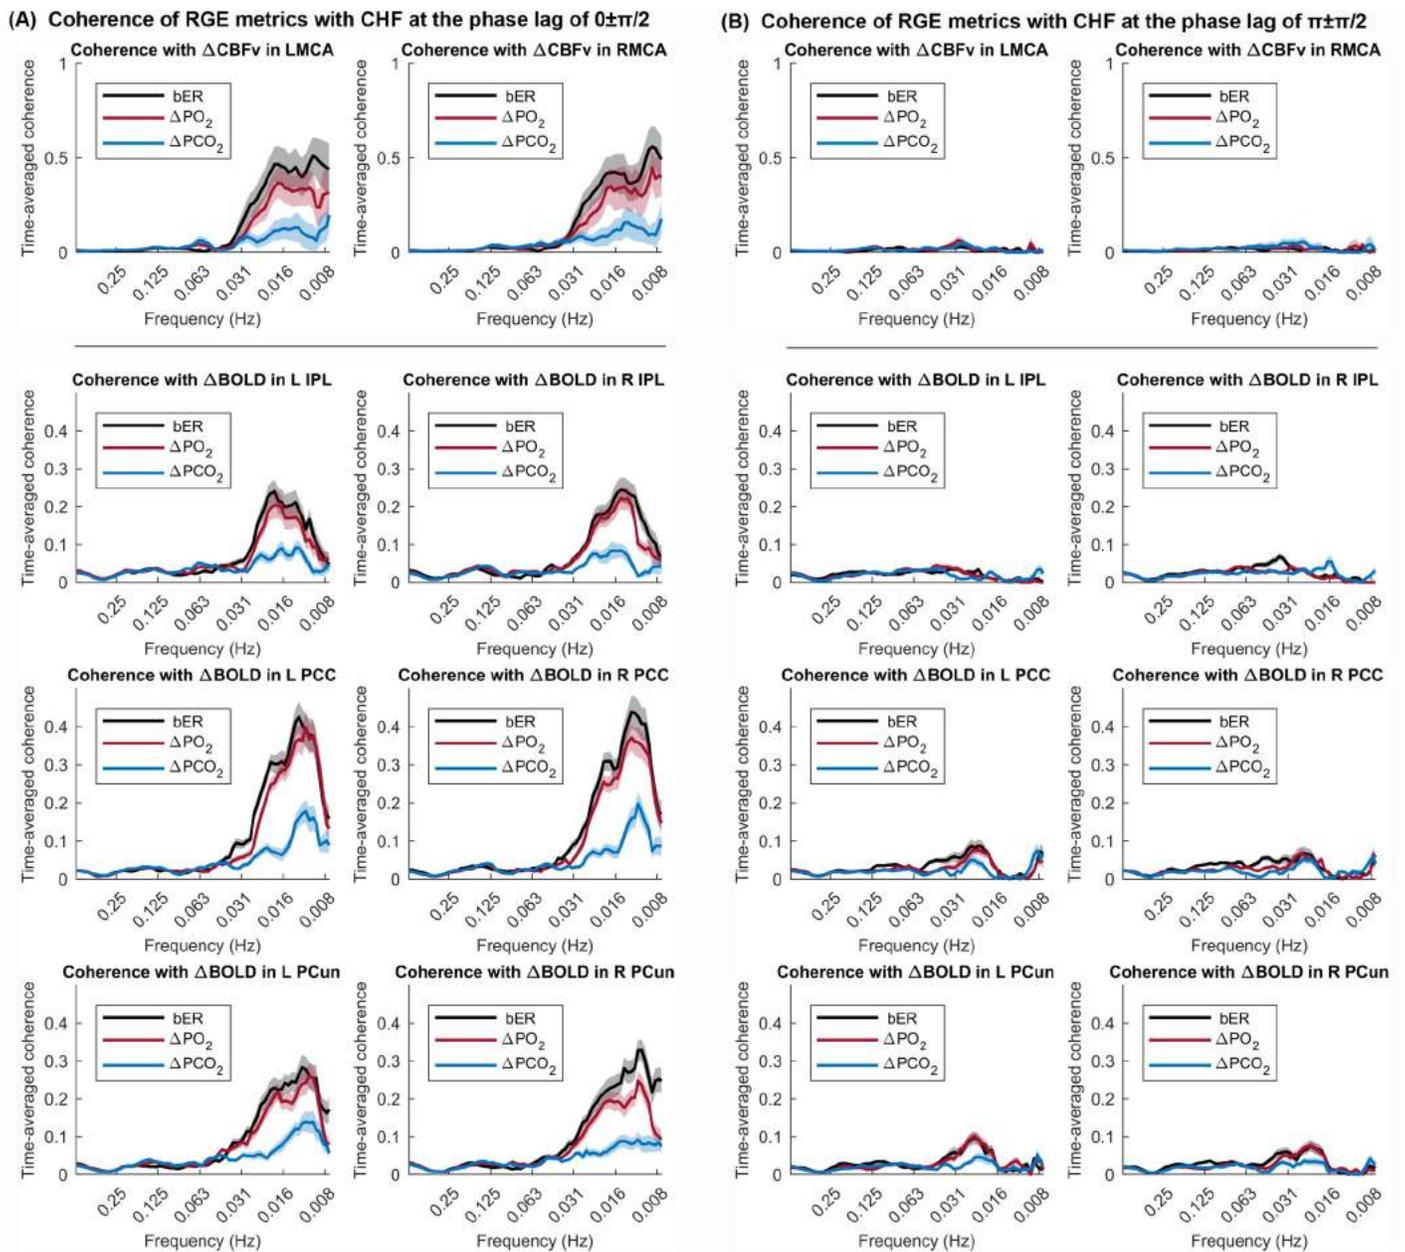

**Fig 2. Correlation between the time series of  $\Delta$ CBFv and RGE metrics during spontaneous breathing.** (A) Time series of  $\Delta$ CBFv in right MCA of a representative subject at rest, without filtering and after applying low pass filter at 0.03Hz. (B) Time series of RGE metrics of bER,  $\Delta$ PO<sub>2</sub>,  $\Delta$ PCO<sub>2</sub>, P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub> acquired simultaneously with  $\Delta$ CBFv of the same subject in (A). (C) Correlation between  $\Delta$ CBFv without filtering and the RGE metrics (left), and that between  $\Delta$ CBFv with low pass filtering at 0.03Hz and RGE metrics (right) of the same subject in (A). (D) For all 13 subjects who participated in TCD sessions, paired comparisons of Fisher's z scores between  $\Delta$ CBFv in left MCA and bER, and those between  $\Delta$ CBFv in left MCA and other RGE metrics besides bER (left), and the paired comparisons of Fisher's z scores between  $\Delta$ CBFv in right MCA and bER, and those between  $\Delta$ CBFv in right MCA and other RGE metrics besides bER (right). Each gray circle represents Fisher's z score from the correlation analysis of  $\Delta$ CBFv and the parameter shown on the x-axis for each subject. The thick middle horizontal line, the box and the vertical rod represent the mean, 95% confidence interval and standard deviation of the group data, respectively.

<https://doi.org/10.1371/journal.pone.0238946.g002>

regions (Fig 4B), while the percentage of significant voxels was smaller in white matter regions. A smaller percentage of gray and white matter voxels showed a significant association of  $\Delta$ BOLD with  $\Delta$ PCO<sub>2</sub>. The maps of paired comparison between voxel $\beta_{bER}$  and voxel $\beta_{\Delta PO_2}$  showed significant difference in the percentage of significant voxels (Fig 4C) in the rostrum and genu of the left corpus callosum. However, the paired comparison between voxel $\beta_{bER}$  and voxel $\beta_{\Delta PCO_2}$  showed a significant difference in the percentage of significant voxels in many areas, including subcortical brain regions, insula and brainstem.

**Regional association between bER and  $\Delta$ BOLD overlapped with many areas of the default mode network.** Group statistical parametric maps of regional association between  $\Delta$ BOLD and RGE metrics in gray matter and brainstem (Fig 5A) were used to compare with the group connectivity map with the seed at left precuneus (Fig 5B) for the same group of 20 subjects in the MRI study. Brain regions showing significant association of  $\Delta$ BOLD with bER and  $\Delta$ PO<sub>2</sub> included precuneus, posterior cingulate, anterior insula, caudate nucleus, superior

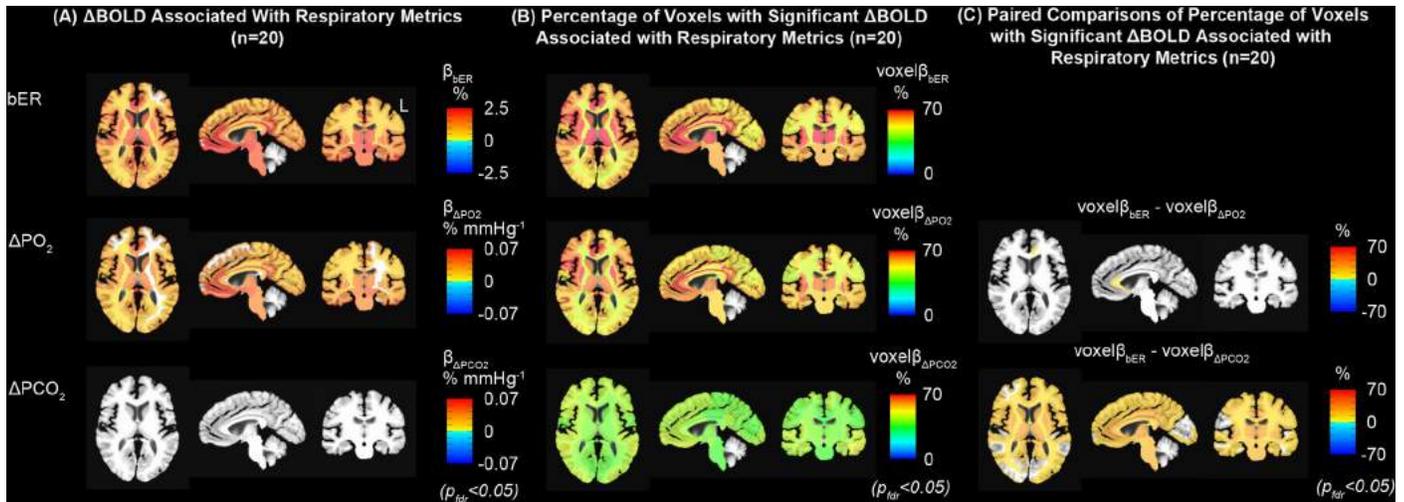

**Fig 3. Time-averaged coherence between time series of RGE metrics and CHF.** The mean time-averaged coherence in the frequency bandwidths from 0.008 to 0.25Hz (A) at the phase lag of  $0\pm\pi/2$ , and (B) at the phase lag of  $\pi\pm\pi/2$ , were plotted (thick color lines). Color shaded areas represent standard error of the mean. Coherence between two time series at the phase lag of  $0\pm\pi/2$  indicates a positive correlation, while a negative correlation is represented by the coherence at the phase lag of  $\pi\pm\pi/2$ . Top panel shows the coherence of RGE metrics with  $\Delta\text{CBFv}$  in LMCA and RMCA in TCD sessions ( $n = 13$ ). The lower panel shows the coherence between RGE metrics and  $\Delta\text{BOLD}$  in the inferior parietal lobule (IPL), posterior cingulate (PCC) and precuneus (PCun) within DMN in MRI sessions ( $n = 20$ ).

temporal and inferior parietal regions. These brain regions overlapped with those in DMN reported by Raichle et al. [23] as well as those reported by Yeo et al. [43] and Choi et al. [44]. Additional regions such as posterior insula, putamen and occipital regions found in our group statistical parametric maps were also shown in the findings by Raichle et al. [23].

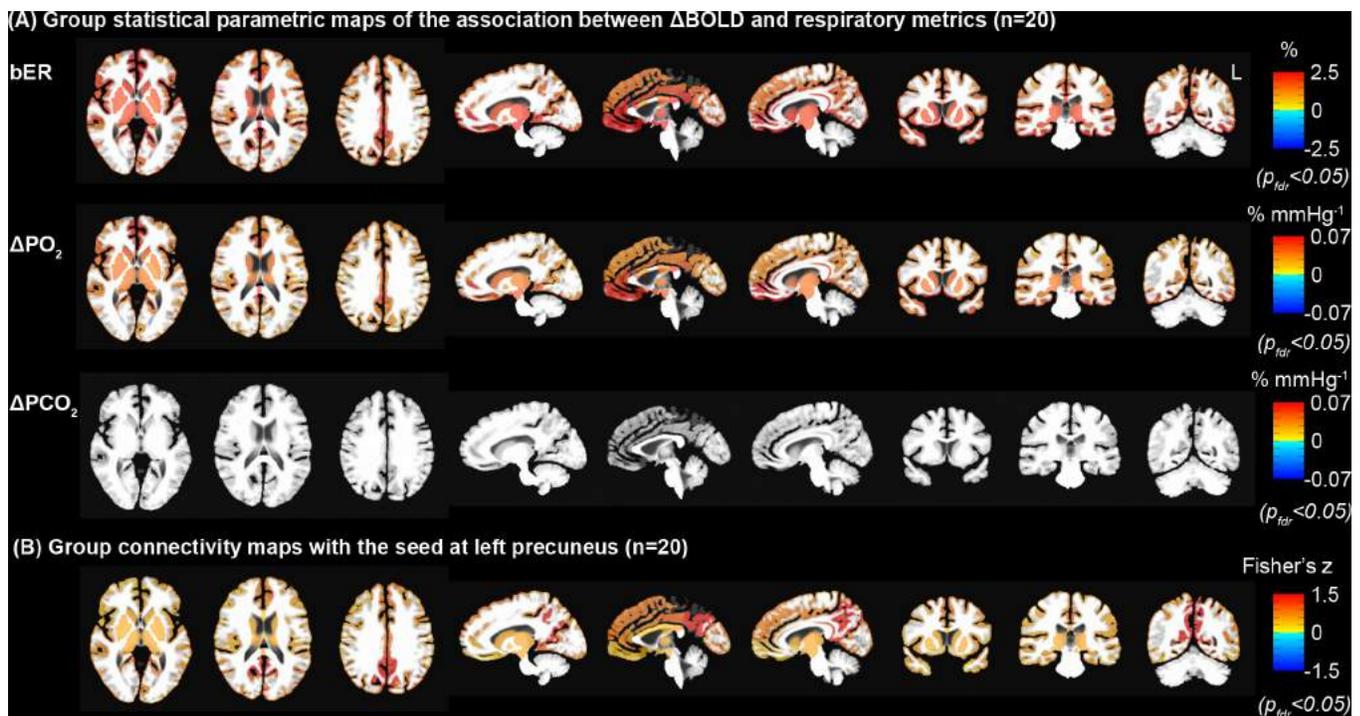

Group analysis of individual connectivity maps demonstrated significant increased connectivity in brain regions similar to the regions showing a significant association between  $\Delta\text{BOLD}$

**Fig 4. Regional association between ΔBOLD and RGE metrics in the MRI sessions.** (A) Group maps showing the regional ΔBOLD per unit change of bER, ΔPO<sub>2</sub> and ΔPCO<sub>2</sub> ( $\beta_{bER}$ ,  $\beta_{\Delta PO_2}$  and  $\beta_{\Delta PCO_2}$ ). (B) Group maps showing the regional percentage of voxels with significant ΔBOLD per unit change of bER, ΔPO<sub>2</sub> and ΔPCO<sub>2</sub> ( $voxel\beta_{bER}$ ,  $voxel\beta_{\Delta PO_2}$  and  $voxel\beta_{\Delta PCO_2}$ ). (C) Paired comparisons of  $voxel\beta$  maps. All the maps had been corrected for  $p_{fdr} < 0.05$ .

and bER (Fig 5). The close match between Fig 5A and 5B from the same BOLD datasets but acquired with independent methods supports that bER is capable of outlining the connectivity among brain regions in the DMN.

**Fig 5. Comparison of statistical parametric maps derived from regression and connectivity analyses.** (A) Group statistical parametric maps of the association between ΔBOLD and RGE metrics (bER, ΔPO<sub>2</sub> and ΔPCO<sub>2</sub>). The white matter was excluded for the comparison with the group connectivity map. (B) Group connectivity map with the seed at left precuneus. ΔPCO<sub>2</sub> was demonstrated to be much weaker than bER and ΔPO<sub>2</sub> in its association with ΔBOLD in the brain regions of DMN. Comparing the top and bottom rows, similar regions of DMN were outlined with two independent methods of bER-CHF coupling and seed-based connectivity analysis. All the maps had been corrected for  $p_{fdr} < 0.05$ .

**Dynamic coherence between bER and  $\Delta$ BOLD in brain regions within DMN.** We used WTC analysis to verify the dynamic coupling between bER and BOLD signal fluctuations in DMN regions such as left and right inferior parietal lobule (IPL), left and right posterior cingulate (PCC), and left and right precuneus (PCun) in all 20 subjects participated in MRI sessions. At the phase lag of  $0 \pm \pi/2$ , we showed that the mean time-averaged coherence between bER and  $\Delta$ BOLD and that between  $\Delta$ PO<sub>2</sub> and  $\Delta$ BOLD reached a value of 0.2 or above in general (Fig 3A, lower panel) at the frequency range between 0.008 and 0.03Hz, while the mean time-averaged coherence between  $\Delta$ PCO<sub>2</sub> and  $\Delta$ BOLD peaked around 0.2 or below (Fig 3A, lower panel). At the phase lag of  $\pi \pm \pi/2$ , the mean time-averaged coherence of all three RGE metrics with  $\Delta$ BOLD stayed below 0.1 at the frequency range between 0.008 and 0.03Hz (Fig 3B, lower panel).

**Dynamic coherence between RVT and  $\Delta$ BOLD in brain regions within DMN.** To confirm that the RVT had little contribution to CHF within the DMN, we used the WTC method to examine the dynamic coupling between RVT and  $\Delta$ BOLD extracted from IPL, PCC and PCun in 10 subjects who had their respiratory tracings measured by a respiratory bellow. We showed that the mean time-averaged coherence between RVT and  $\Delta$ BOLD at the phase lag of  $0 \pm \pi/2$  increased between 0.016 and 0.031Hz, and reduced at the frequency below 0.016Hz where the mean time-averaged coherence started to increase at the phase lag of  $\pi \pm \pi/2$  (S5 Fig). The frequency distribution of coherence of CHF with RVT is shown to be very different from that with bER.

**Regional CVR maps under exogenous CO<sub>2</sub> challenge and during spontaneous breathing.** Under exogenous CO<sub>2</sub> challenge, most of the brain regions showed increased CVR<sub>CO<sub>2</sub>-PETCO<sub>2</sub></sub> in the subject group, especially thalamus, insula and putamen (S6 Fig). During spontaneous breathing, increased  $\beta_{\text{bER}}$  was found in most of the brain regions, while no significant association indicated by  $\beta_{\Delta\text{PCO}_2}$  were shown in most of the brain regions. The CVR map during spontaneous breathing indicated by  $\beta_{\text{bER}}$  resembled the CVR map under exogenous CO<sub>2</sub> challenge indicated by CVR<sub>CO<sub>2</sub>-PETCO<sub>2</sub></sub>.

## Discussion

There has been no previous study on the dynamic interactions between low frequency fluctuations of resting state CHF ( $\Delta$ CBFv and  $\Delta$ BOLD) and those of all three RGE metrics of bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>. However, results in this study support such interactions even though the physiological mechanisms are still unclear. The time series of  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> were shown to be interdependent but non-redundant. The prominent oscillations of bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> were characterized by periods of 0.5 to 2 minutes (0.008–0.03Hz) and were coherent with CHF in this frequency range. The coherence of CHF with bER or with  $\Delta$ PO<sub>2</sub> was much stronger than the coherence of CHF with  $\Delta$ PCO<sub>2</sub> in the frequency range between 0.008Hz and 0.03Hz. bER was shown in some brain regions to be superior to  $\Delta$ PO<sub>2</sub> in the association with CHF. Brain regions with the strongest bER-CHF coupling overlapped with many areas of DMN. Taken together, our study provides evidence that resting state CHF at low frequency show the strongest association with fluctuations attributed to bER.

## Oscillations of $\Delta$ PO<sub>2</sub> and $\Delta$ PCO<sub>2</sub> are interdependent but not necessarily redundant

The  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> were often considered to be redundant [4, 6, 16]. In the present study, the average value of the correlation strength of around 0.8 and the relatively large spread of the correlation between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> demonstrated that while  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> were interdependent they were not redundant to each other (Fig 1). Respiratory data during spontaneous

breathing in healthy infants and adults were consistent with ours, showing that P<sub>ET</sub>O<sub>2</sub> and P<sub>ET</sub>CO<sub>2</sub> were correlated but not redundant [13, 17, 18].

The interdependent but non-redundant oscillations of  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> during spontaneous breathing at the normoxic level are also supported by the findings of feedback loops involving the interaction among chemoreceptors, and blood gases demonstrated in many earlier studies on animal models [10, 45–48]. Most of these studies on the role of PO<sub>2</sub> to stimulate peripheral chemoreceptors at the carotid body had been focused on hypoxia at PO<sub>2</sub> level less than 60 mmHg [10, 49] where chemoreceptor activities rose quickly in a hyperbolic fashion. However, Biscoe et al. [45] showed that peripheral chemoreceptor activities were present from normoxia to hyperoxia up to arterial PO<sub>2</sub> level of 190 mmHg and beyond. Lahiri et al. [48] reported that the stimulus thresholds of arterial PO<sub>2</sub> and PCO<sub>2</sub> for peripheral chemoreceptors were largely interdependent under normoxic conditions. A drop in arterial PO<sub>2</sub> was routinely accompanied by increased chemoreceptor activities as well as an enhanced sensitivity of carotid chemoreceptors to arterial PCO<sub>2</sub>. While research on the mechanisms of interaction between peripheral and central chemoreceptors to optimize systemic blood gases is on-going [9–11], the chemoreceptor activities reported in these studies highlight the interdependence of PO<sub>2</sub> and PCO<sub>2</sub> which work synergistically to regulate the blood supply to the brain. bER can be one of the appropriate metrics to be used in the study of such synergism between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>. The superiority of bER over  $\Delta$ PCO<sub>2</sub> in correlating with CHF is likely to be attributed partly to the ratio format of bER enabling a reduction of ventilatory fluctuations common to  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>, and partly to the physiological role of bER which takes into account the interaction between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>. Besides, a regression model of  $\Delta$ CBFv or  $\Delta$ BOLD vs RGE metrics, including both  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub> as regressors would suffer from collinearity due to the correlation between  $\Delta$ PCO<sub>2</sub> and  $\Delta$ PO<sub>2</sub>.

Interestingly, the spread of correlation strengths between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> as well as those between bER and  $\Delta$ PO<sub>2</sub> were different between TCD and MRI sessions (Fig 1). Correlation strengths might change in response to different factors which could include the postures of sitting up vs lying down, the noises, or the level of stress from the surroundings. Participants were sitting in an open and quiet environment in TCD sessions while they were lying down in supine position in a noisy environment of the MRI scanner bore. A change from the supine posture to sitting upright was reported to be associated with a redistribution of both blood flow and ventilation in the lungs, which affected the arterial PO<sub>2</sub> [50–53]. While it is interesting to observe the differences in the correlation strength among RGE metrics between TCD and MRI sessions, the details of such mechanisms are outside the scope of our current study.

### Dynamic coupling between CHF and RGE metrics of bER, $\Delta$ PO<sub>2</sub> and $\Delta$ PCO<sub>2</sub>

Correlation and coherence analyses showed the dynamic coupling between CHF ( $\Delta$ CBFv and  $\Delta$ BOLD) and RGE metrics of bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> in both TCD (Figs 2 and 3) and MRI sessions (Figs 3 and 4). Had  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> been redundant, their correlation and coherence with CHF would be expected to be the same, and there should be weak correlation and coherence of CHF with bER. In contrast, comparing with  $\Delta$ PO<sub>2</sub> and bER, we found that  $\Delta$ PCO<sub>2</sub> had moderate to weak correlation with  $\Delta$ CBFv (Fig 2). The map of  $\beta_{\Delta$ PCO<sub>2</sub> for a single individual showed fewer pixels with a significant association between  $\Delta$ BOLD and  $\Delta$ PCO<sub>2</sub> (S4A Fig). Group analysis of regional  $\beta_{\Delta$ PCO<sub>2</sub> showed however almost a “null” map as only a few brain regions (insula, medial orbitofrontal and temporal areas) showed association between  $\Delta$ PCO<sub>2</sub> and  $\Delta$ BOLD (S4B Fig) but such association did not reach statistical significance after correcting for multiple comparisons (Fig 4). Our group averaged result was consistent with the

findings in the study by Golestani et al. [16], where large inter-individual variability was demonstrated in the brain maps of regressing BOLD signal changes on P<sub>ET</sub>CO<sub>2</sub> during spontaneous breathing.

The interaction between  $\Delta$ PCO<sub>2</sub> and CHF is accompanied by an interaction between  $\Delta$ PO<sub>2</sub> and CHF. However, the mechanisms behind the superiority of  $\Delta$ PO<sub>2</sub> over  $\Delta$ PCO<sub>2</sub> in association with CHF, especially at the frequency range of 0.008–0.03Hz, remain unclear. A possible factor may be related to the difference in the O<sub>2</sub> and CO<sub>2</sub> dissociation curves, which are associated with the magnitude of the PO<sub>2</sub> and PCO<sub>2</sub> variations in time [13]. During spontaneous breathing, the PO<sub>2</sub> varies from approximately 150mmHg in inspired air to 100mmHg in expired air at the top horizontal asymptote of the sigmoidal O<sub>2</sub> dissociation curve, where it is associated with only a small change in oxygen saturation. On the contrary, the CO<sub>2</sub> dissociation curve is more linear. With the Haldane effect, O<sub>2</sub> affects the affinity of hemoglobin for CO<sub>2</sub>. Given the small fluctuations of oxygen saturation, a rather significant change in PO<sub>2</sub> can, therefore, be associated with a minor change in PCO<sub>2</sub>. The larger oscillation amplitude of  $\Delta$ PO<sub>2</sub> in comparison with that of  $\Delta$ PCO<sub>2</sub> was observed by our team (Fig 2 and Table 2) and by Lenfant et al. [13]. An additional factor that was suggested by Lenfant et al. is the variation in the distribution of the ventilation-to-perfusion ratio (V/Q) in the lungs. Lenfant et al. reported that the alveolar-arterial difference in PO<sub>2</sub> decreased as V/Q increased, while that in PCO<sub>2</sub> remained nearly constant and independent of the changes in V/Q. The temporal oscillation of the V/Q distribution could then cause a more considerable change in PO<sub>2</sub> than in PCO<sub>2</sub>. That also raises an intriguing idea for future research to examine any possible relationship between CHF and fluctuations in V/Q. The superiority of  $\Delta$ PO<sub>2</sub> over  $\Delta$ PCO<sub>2</sub> in association with CHF suggests a potentially important implication that CHF is more sensitive to the demand of the supply of O<sub>2</sub> than of the removal of CO<sub>2</sub>. In addition to our studying of healthy subjects, exploring the interaction between CHF and RGE metrics in patients with known disorders may increase the understanding of the stronger coupling of CHF with bER and  $\Delta$ PO<sub>2</sub> than with  $\Delta$ PCO<sub>2</sub>.

### Brain regions with the strongest bER-CHF coupling overlapped with many regions of default mode network

We used the resting state connectivity method with the seed at the left precuneus to outline the areas within DMN (Fig 5B). We found that brain regions with the strongest association between bER and  $\Delta$ BOLD (Fig 5A) overlapped with many areas of DMN. Such strong association may be attributed to DMN showing higher metabolic and hemodynamic activities at rest than other parts of the cortex [23]. Fluctuations of systemic gases can be under the influences of ambient (exogenous) gases and/or systemic (endogenous) gases due to metabolism as well as feedbacks between chemoreceptors. Since the brain is one of the major shareholders of systemic blood flow [54] and metabolism [55, 56] at rest, any mechanisms that help to preserve cerebral metabolism and CBF within the normal range in the homeostatic regulatory process [12] may leave a signature in the CHF.

In our resting state experiments, CHF were measured on participating individuals during spontaneous breathing. No cognitive, motor, sensory, visual and gas challenges were applied to the participants. The internal environment of the body was steady, and major body organs had constant autonomic communication with the brain back and forth. At rest, background cerebral neurovascular coupling activities are characterized by DMN [23], and RGE metrics can be related to basal activities of the whole body. Hence it would be reasonable for RGE metrics to couple better with DMN than with other brain networks. bER which showed the strongest correlation with CHF is therefore expected to interact more with DMN. The bER-CHF

coupling in DMN found in our study is consistent with the findings in previous studies that CBF and DMN connectivity were altered in individuals with disrupted systemic metabolism [57–64].

### **Physiological processes that may be associated with the coherence between CHF and bER at the low frequency range of 0.008–0.03Hz**

The CHF coherence with RGE metrics at the low frequency range of 0.008–0.03Hz may be associated with low frequency physiological processes in the brain that are grouped in B-wave frequency bandwidth. B-waves with a period of 0.5 to 2 minutes (0.008–0.03Hz) have been reported to be related to autoregulation of microvasculature, spontaneous rhythmic oscillations in intracranial pressure (ICP), and intrinsic brainstem rhythm that leads to cerebral blood volume modulation [65, 66]. B-waves may also independently reflect the neurovascular coupling process by altering vascular diameters to ensure the delivery of O<sub>2</sub> and other circulating metabolites through the contractile properties of pericytes or vascular smooth muscle cells [67–70]. Since oscillations of B-waves are not always associated with the change of arterial CO<sub>2</sub> [66], it would be interesting to pursue further the relationship between B-waves and all three of our RGE metrics as well as resting state CHF.

The coherence of CHF with RGE metrics at the frequency of 0.008–0.03Hz may also be related to a proposed mechanism to remove cerebral metabolic waste. In the glymphatic model [71], cerebral metabolic waste was hypothesized to be cleared from the brain via the perivascular space by vascular pulsation. The actual type of vascular pulsation remains to be determined. To describe possible mechanisms for glymphatic convection, Kiviniemi et al. [72] identified a very slow pulsation found in cerebrospinal fluid (0.001–0.023Hz), which is again in the frequency range similar to the oscillations of the RGE metrics.

In the peripheral circulation, laser Doppler measurements showed that the endothelial activity oscillated at the frequency of 0.0096–0.021Hz [73, 74], which is within the same low frequency range of CHF and fluctuations of RGE metrics with a particular interest on bER based on our results. Is there any direct relationship between oscillatory cycles of peripheral endothelial activity and CHF? Considering the model of diving reflex [75] where an increase in CBF is associated with peripheral vasoconstriction, is it possible that the decrease in peripheral blood flow is mirrored by an increase in CBF in a homeostatic process during spontaneous breathing? Future research can be directed to explore the association between bER, CHF and peripheral (skin) blood flow oscillations at the low frequency range of 0.008–0.03 Hz.

Separate from the B-waves and glymphatic model, we do not consider heart rate (HR) or heart rate variability (HRV) to be a major contributing factor for the role of RGE metrics in CHF. Even though HR and HRV had been reported to contribute to low frequency fluctuations, the peaks of coherence between  $\Delta$ BOLD and HR/HRV were at the frequency of 0.05Hz or above (period ~30–42 seconds) [5, 76] which are different from our findings that RGE metrics were coherent with CHF between 0.008 and 0.03Hz.

### **Ventilatory volume fluctuations are not the primary origin of our finding on the association between CHF and the fluctuations of RGE metrics**

We should point out that ventilatory volume fluctuations are unlikely to be the cause of our observed interaction between CHF and RGE metrics. Respiratory variability, namely changes in respiration volume per time or RVT that had been shown to have a strong correlation with the change in respiratory volume [14] had also been discussed as a possible source for DMN activities [3]. However, a number of considerations showed that RVT did not provide the answers to our findings on the differences observed between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> in their

interaction with CHF. First, RVT would be expected to have the same effect on the time courses of  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ . Second, bER, being a ratio of  $\Delta\text{PO}_2/\Delta\text{PCO}_2$ , reduces the contribution of ventilatory volume fluctuations to the interaction between bER and CHF. Previous studies showed that the relationship between the time courses of  $\text{P}_{\text{ETCO}_2}$  and RVT was unclear [14, 16]. There was only a mild coherence between  $\text{P}_{\text{ETCO}_2}$  and RVT [14]. The authors in these studies showed that changes in RVT had a weaker correlation with BOLD signal changes when compared with  $\text{P}_{\text{ETCO}_2}$  [16, 77]. Such results are not surprising as  $\text{P}_{\text{ETCO}_2}$  is supposed to play a more direct role than ventilation to modulate CHF [3, 4]. Besides, the time course of RVT is less than ideal as the numerator of RVT acquired with a respiratory bellow indicates the chest excursion, while respiratory volume is the volume of air breathing in or out. Our coherence analysis showed that  $\Delta\text{BOLD}$  at DMN regions were less coherent with RVT than with bER or  $\Delta\text{PO}_2$  (S5 Fig). RVT showed coherence with  $\Delta\text{BOLD}$  at the phase lag of  $0\pm\pi/2$  between 0.016 and 0.031Hz but the coherence increased slightly between 0.008 and 0.016Hz at the phase lag of  $\pi\pm\pi/2$ . The coherence findings of RVT were also different from those of  $\Delta\text{PCO}_2$ . The frequency bandwidths and the phase differences seen in our coherence of RVT with  $\Delta\text{BOLD}$  are consistent with those reported by Van den Aardweg [14] even though his team was measuring respiratory volume from a facemask. While coherence frequency bandwidths at different phase lags may be referring to the responses from different chemoreceptors (e.g. central vs peripheral), the relationship between the time courses of  $\text{P}_{\text{ETCO}_2}$  and RVT is still unclear.

### Technical issues that have been addressed

In this study, we used TCD to acquire CHF in addition to using fMRI. One advantage of TCD is its high temporal resolution with less concern on the aliasing effect of high frequency hemodynamic signal. Potential technical confounds like gas sampling at two gas analyzers and technical delay on the time series were also addressed in the data acquisition protocol. In the gas sampling circuit, the same gas sample volume was used in both CO<sub>2</sub> and O<sub>2</sub> analyzers at the same gas sampling flow rate. The technical delay on the time series of gas measurements due to transit time of respiratory gases and the response of the equipment were corrected in the preprocessing of the physiological signals.

In the preprocessing of fMRI data, we did not apply RETROICOR [78] to reduce ventilatory and cardiac ‘interference’ in the BOLD signals because the heart rate was reported to contribute to BOLD signals mainly at 0.3Hz or above [76] which was above the frequency bandwidths of interest (below 0.03Hz) in this study. Our findings of the correlation between  $\Delta\text{BOLD}$  and RGE metrics in healthy subjects were supported by the CBFv data which were acquired with TCD at a sampling rate of 100Hz on the same group of subjects. There is no concern of aliasing of high frequency cardiac signal into our CBFv signal at low frequency range below 0.03Hz. In Fig 2, we also demonstrated that the preprocessing step for CBFv signals like data smoothing did not change the correlation ranking of  $\Delta\text{CBFv}$  with bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ .

In our fMRI regression analysis, we did not convolve the RGE metrics with a specific respiratory response function (RRF) which was commonly used to convolve with RVT or  $\text{P}_{\text{ETCO}_2}$  to improve its correlation with  $\Delta\text{BOLD}$  [3, 4, 6, 16]. The reason is that RRF is unnecessary when our primary objective is comparing the association of different RGE metrics (bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$ ) with  $\Delta\text{BOLD}$ . If the application of RRF improves the correlation of  $\Delta\text{PCO}_2$  with  $\Delta\text{BOLD}$ , it will also improve the correlation of  $\Delta\text{PO}_2$  or bER with  $\Delta\text{BOLD}$ . There is no justification for applying RRF to only  $\Delta\text{PCO}_2$  and not to  $\Delta\text{PO}_2$ . Applying the same RRF to all of the RGE metrics should have little effect on how one RGE metric ranks against other RGE metrics in its association with  $\Delta\text{BOLD}$ . Another approach to state that convolution of RGE metrics

with RRF is not applicable in our case because our research question is ‘Which RGE metric contributes more to  $\Delta$ BOLD?’ whereas studies that took up RRF [3, 4, 6, 16] focused on a separate question of ‘Which brain regions have stronger  $\Delta$ BOLD responses to RVT or P<sub>ET</sub>CO<sub>2</sub>?’ With a different research question, it was reasonable for those previous studies to focus on convolving the RVT or P<sub>ET</sub>CO<sub>2</sub> time series with RRF which identified the portion of the  $\Delta$ BOLD that was not directly accounted for by the time series of RVT or P<sub>ET</sub>CO<sub>2</sub>.

### Technical issues that need to be addressed in the future

Even though  $\Delta$ PO<sub>2</sub> is related to the partial pressure of O<sub>2</sub> utilized in the whole body, we cannot simply substitute  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> for O<sub>2</sub> uptake (VO<sub>2</sub>) and CO<sub>2</sub> release (VCO<sub>2</sub>). O<sub>2</sub> uptake and CO<sub>2</sub> release require extra elements like respiratory minute volume (sometimes normalized for body weight) and are typically evaluated as a steady state of RGE data obtained by averaging the breath-by-breath signal over minutes. A measurement of breath-by-breath VO<sub>2</sub> and VCO<sub>2</sub> inside the MRI scanner in addition to the collection of  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> was not included in our study. Given the physical constraint of the MRI settings, we collected  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> using a nasal tubing. We will leave the possibility of measuring VO<sub>2</sub> and VCO<sub>2</sub> during MRI to future neuroimaging research. However, under specific conditions, some information extracted from  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> can be related to that from VO<sub>2</sub> and VCO<sub>2</sub>. As mentioned above, bER has the explicit influence on suppressing the ventilatory volume when we are taking the ratio of  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub>. We, therefore, consider the possibility of bER or equivalently  $\Delta$ PO<sub>2</sub>/ $\Delta$ PCO<sub>2</sub> being a surrogate for breath-by-breath VO<sub>2</sub>/VCO<sub>2</sub> at rest.

As the vasodilatory role of CO<sub>2</sub> to modulate CBF is an entrenched belief, it is natural to gravitate towards the explanation that association between RGE metrics and CHF must be resulting from “the effect of CO<sub>2</sub> which reflects in O<sub>2</sub>”. However, the model of CO<sub>2</sub> being the sole agent to interact with CHF remains at variance with our findings of non-redundancy between  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> in this study. Therefore, further investigations on the roles of bER,  $\Delta$ PO<sub>2</sub> and  $\Delta$ PCO<sub>2</sub> in their association with CHF would be warranted.

### Potential application of bER in the evaluation of CVR

While bER was prominently coupled with CHF within DMN, bER was also coupled, albeit to a less extent, with CHF in the rest of voxels throughout the whole brain. Therefore bER can be used instead of  $\Delta$ PCO<sub>2</sub> as a regressor to evaluate CVR to spontaneous breathing (S6 Fig). The question is whether the expected small perturbations provided by RGE metrics during spontaneous breathing could have any clinical utility. The previous study on the successful identification of local vascular deficits of moyamoya patients [79] had already been reported for CVR to P<sub>ET</sub>CO<sub>2</sub> obtained in spontaneous breathing. In our recent study, we found that bER is more robust than P<sub>ET</sub>CO<sub>2</sub> in characterizing the cerebral hemodynamic responses to brief breath hold challenge in healthy adults [15]. Future studies will clarify the sensitivity and benefits of imaging local vascular deficits using bER instead of P<sub>ET</sub>CO<sub>2</sub> from spontaneous breathing.

Imaging of bER-CHF coupling may open up opportunities for potential clinical diagnosis and intervention. The clinical potential of RER at rest has been reported for decades. RER, the reciprocal of the steady state mean value of bER, has been reported to change significantly with age [80] and with diseases attributed to respiratory [81], liver [63], cardiac [82] and neuronal [83] dysfunctions. Instead of focusing on the steady state results, our manuscript centers more on the dynamic fluctuations of bER, as a separate metric of interest. The bER-CHF coupling may offer an alternative approach to map brain regions interacting with systemic homeostatic processes besides resting state connectivity analysis for the connections among brain regions [2] and task-induced negative BOLD responses [23]. Since abnormal DMN can be an

indicator of neuronal disorders [84, 85], future studies on different patient populations may help clarify the meaning of abnormal bER-CHF coupling. Our brain-body coupling framework may be applied in the investigation of brain responses to voluntary respiratory techniques like meditation, yoga breathing or tai-chi [86–93] to manipulate RGE for intervention purpose. Instrument assisted respiratory techniques like the Bi-level Positive Airway Pressure (BiPAP) [94–96] that applies to sleep apnea or Amyotrophic Lateral Sclerosis (ALS) may also be considered.

## Conclusion

While the physiological mechanisms are not completely known for the interaction between CHF and RGE metrics of bER,  $\Delta PO_2$  and  $\Delta PCO_2$ , our findings provide evidence that fluctuations of RGE metrics are associated with resting state CHF at a low frequency between 0.008Hz and 0.03 Hz. Both bER and  $\Delta PO_2$  are more superior to  $\Delta PCO_2$  in association with CHF while CHF could correlate more strongly with bER than with  $\Delta PO_2$  in some brain regions. Brain regions with the strongest bER-CHF coupling overlap with many areas of DMN. In addition to offering a physiological model to characterize the contribution of gas exchange elements in the low frequency resting state fluctuations, our findings provide new directions to the study of brain-body interaction. Assessing the validity of the popular CO<sub>2</sub>-only hypothesis as well as other alternative hypotheses to explain our results of bER-CHF coupling remains an on-going project.

## Supporting information

### S1 Fig. Definition of end inspiration and end expiration on the time series of RGE metrics.

A segment of 90-second time series of  $\Delta CBFv$  in left MCA and physiological changes including breath-by-breath bER,  $\Delta PO_2$ ,  $\Delta PCO_2$ ,  $P_{ET}O_2$  and  $P_{ET}CO_2$  measured by gas analyzers and respiration time series (Resp) measured by respiratory bellow in a representative subject during spontaneous breathing in TCD session. Open circles represent end expiration while closed circles represent end inspiration. Positive phases with deflection above zero on the respiration time series represent inspiration and negative phases with deflection below zero represent expiration. The inspiratory and expiratory phases of each respiratory cycle on the time series of  $P_{ET}O_2$  and  $P_{ET}CO_2$  are verified by those on respiration time series. The timing for open (end expiration) and closed (end inspiration) circles in green is the same as those in red and blue.

(TIF)

### S2 Fig. Correlation of $\Delta CBFv$ with the ratio as well as the product of $\Delta PO_2$ and $\Delta PCO_2$ in a representative subject.

Time series of  $\Delta CBFv$  and bER normalized to its mean (*upper left*). Moderate correlation was shown between  $\Delta CBFv$  and bER (*upper right*). Time series of  $\Delta CBFv$  and the product of  $\Delta PO_2$  and  $\Delta PCO_2$  ( $\Delta PO_2 \times \Delta PCO_2$ ) normalized to its mean (*lower left*).

Weak correlation was shown between  $\Delta CBFv$  and  $\Delta PO_2 \times \Delta PCO_2$  (*lower right*).

(TIF)

### S3 Fig. Wavelet transform coherence analysis between bER and $\Delta CBFv$ in a representative subject.

(A) Time series of bER and  $\Delta CBFv$  measured in right MCA of a representative subject at rest. (B) The squared wavelet coherence between these two time series. Squared wavelet coherence is plotted with x-axis as time and y-axis as scale which has been converted to its equivalent Fourier period. The magnitude of wavelet transform coherence ranges between 0 and 1, where warmer color represents stronger coherence and cooler color represents weaker coherence. Areas inside the ‘cone of influence’, which are locations in the time-frequency

plane where edge effects give rise to lower confidence in the computed values, are shown in faded color outside of the conical contour. The statistical significance level of the wavelet coherence is estimated using Monte Carlo methods and the 5% significance level against red noise is shown as thick contour. The phase angle between the two time series, with bER leading  $\Delta$ CBFv, at particular samples of the time-frequency plane is indicated by an arrow (rightward pointing arrows indicate that the time series are in phase or positively correlation, leftward pointing arrows indicate anticorrelation and the downward pointing arrows indicate phase angles of  $\pi/2$ ). There are four different ranges of phase lags:  $0+\pi/2$ ,  $0-\pi/2$ ,  $\pi-\pi/2$ , and  $\pi+\pi/2$ . (C) Time-averaged coherence at four different phase lags of  $0+\pi/2$ ,  $0-\pi/2$ ,  $\pi-\pi/2$ , and  $\pi+\pi/2$ . At each phase lag range, time-averaged coherence was defined as the total significant coherence at each scale where the wavelet coherence magnitude exceeded 95% significance level, normalized by the maximum possible coherence outside the cone of influence, i.e. inside the conical contour, at that particular scale and phase lag range.

(TIF)

**S4 Fig. Regional association between  $\Delta$ BOLD and RGE metrics in a representative subject and in group.**

(A) Brain maps of  $\beta_{\text{bER}}$ ,  $\beta_{\Delta\text{PO}_2}$  and  $\beta_{\Delta\text{PCO}_2}$  in a representative subject after correcting for multiple comparisons. (B) Group maps of regional  $\beta_{\text{bER}}$ ,  $\beta_{\Delta\text{PO}_2}$  and  $\beta_{\Delta\text{PCO}_2}$  before correcting for multiple comparisons for all the subjects included in the MRI sessions.

(TIF)

**S5 Fig. Distribution of time-averaged coherence between time series of respiratory volume per unit time (RVT) and  $\Delta$ BOLD in brain regions within the DMN.**

The mean time-averaged coherence between time series of RVT and  $\Delta$ BOLD at the phase lags of  $0\pm\pi/2$  and  $\pi\pm\pi/2$  (thick color lines) in the brain regions of the inferior parietal lobule (IPL), posterior cingulate (PCC) and precuneus (PCun) of the left brain (*left panel*) and of the right brain (*right panel*) ( $n = 10$ ). Color shaded areas represent standard error of the mean. Coherence between two time series at the phase lag of  $0\pm\pi/2$  indicates positive correlation, while negative correlation is represented by the coherence at the phase lag of  $\pi\pm\pi/2$ .

(TIF)

**S6 Fig. Regional CVR maps under exogenous CO<sub>2</sub> challenge and regional association between  $\Delta$ BOLD and RGE metrics during spontaneous breathing.**

The CVR map during spontaneous breathing indicated by  $\beta_{\text{bER}}$  changes resembled the CVR map under exogenous CO<sub>2</sub> challenge indicated by  $\text{CVR}_{\text{CO}_2\text{-PETCO}_2}$ .

(TIF)

**S1 Table. Correlation among RGE metrics.** Strength of correlation indicated by Pearson's correlation coefficients among respiratory metrics including bER,  $\Delta\text{PO}_2$  and  $\Delta\text{PCO}_2$  in all subjects who participated in TCD sessions ( $n = 13$ ), and those who participated in MRI sessions ( $n = 20$ ).

(DOCX)

**S2 Table. Correlation between RGE metrics and  $\Delta$ CBFv in TCD sessions.** Strength of correlation indicated by Pearson's correlation coefficients between  $\Delta$ CBFv and RGE metrics including bER,  $\Delta\text{PO}_2$ ,  $\Delta\text{PCO}_2$  and  $\text{P}_{\text{ET}}\text{CO}_2$  ( $n = 13$ ). Numbers in brackets next to Pearson's correlation coefficients indicate p values from individual correlation analyses. The bottom row shows the mean values of Fisher's Z scores transformed from Pearson's correlation coefficients in groups. Numbers in brackets next to mean Fisher's Z scores indicate p values in the paired comparisons.
